## 2 ABSTRACT

3 VATD (volcanic ash transport and dispersion) models simulate atmospheric transport of ash  
4 starting from a source originating at the volcano represented by concentration of ash with height.  
5 Most VATD models use a source of some prescribed shape calibrated against an empirical  
6 expression for the height-mass eruption rate (MER) relation. The actual vertical ash distribution  
7 in volcanic plumes usually vary from case to case and have complex dependencies on eruption  
8 source parameters and atmospheric conditions. We present here for the first time the use of a  
9 3D (three-dimensional) plume model to represent the ash cloud source without any assumption  
10 regarding plume geometry. By eliminating assumed behavior associated with a semi-empirical  
11 plume geometry, the predictive skill of VATD simulations is greatly improved. To date, no VATD  
12 simulation adopts initial conditions created from first principles based on a 3D plume simulation.  
13 We use our recently developed volcanic plume model based on a 3D smoothed-particle hydrody-  
14 namic Lagrangian method, and couple the output to a standard Lagrangian VATD model. We  
15 apply the coupled model to historical eruptions to illustrate the effectiveness of the approach. The  
16 importance of the source model is shown in sensitivity analyses, which show that the simulation  
17 of volcanic ash transport and dispersion is much more sensitive to the source geometry than it is  
18 to all other input parameters. Further investigation reveals that initial particle distribution in the  
19 vertical direction has more impact on transport of ash clouds than does the horizontal distribution.  
20 Comparison with satellite data indicates that ash particles are concentrated through the depth of  
21 the volcanic umbrella cloud, and much lower than observed maximum plume height.

## 1 INTRODUCTION

Volcanic ash, the fine-grained fraction of tephra can be widely dispersed to synoptic and global scales, and can lead to a degradation of air quality and pose threats to aviation (Tupper et al., 2007). Identification, tracking and modeling the future movement of volcanic ash help route and schedule flights to avoid ash clouds. Numerical estimation of ash distribution using known and forecast wind fields is necessary if we are to accurately predict ash cloud propagation and spread. Numerous VATD (volcanic ash transport and dispersion) models have been developed by both civil and military aviation, and meteorological agencies to provide forecasts of ash cloud motion (Witham et al., 2007). New techniques have been integrated into VATDs to satisfy increasing demands for different types of output, model accuracy and forecast reliability. This contribution explores a method for creating initial conditions for VATD simulations, which promises to improve prediction capability and accuracy.

Fero et al. (2009) and Stohl et al. (2011) showed that initial source conditions have significant effects on simulation of volcanic ash transport. Traditional VATD simulation requires key global descriptors of the volcanic plume, especially plume height, grain size, eruption duration and mass loading, or alternatively, a mass eruption rate (MER). No matter how these global descriptors are obtained, they are used to furnish the initial conditions for VATDs in the form of a line-source term of a spatio-temporal distribution of particle mass. It is a common practice to pick values for these global descriptors using an empirical expression for the height-MER relation. The empirical expression is written as a function of several parameters, including the key global descriptors. The values for the descriptors can also be found by parameter calibration (e.g. Fero et al., 2008, 2009; Stohl et al., 2011; Zidikheri et al., 2017). One-dimensional (1D) plume models serve as an alternative option to provide values. For example, Bursik et al. (2012) used the 1D model puffin (Bursik, 2001) to generate estimates of mass eruption rate and grain size. In some cases, an extra step is adopted to spread ash particles from the line source horizontally, resulting in an initial ash cloud in 3D space. The horizontal spreading depends on an empirical expression. For example, the VATD model Puff spreads particles from the line source uniformly in the horizontal direction within a given radius using an empirical expression generated from the output of puffin. Considering the complexities of volcanic eruptions, the actual ash distribution in the initial ash cloud should vary from case to case and with time, making it difficult to find one general expression that is suitable for all cases. It is useful therefore to investigate alternative ways for creating initial ash clouds without assumptions regarding plume geometry, or numerical inversion. This provides the major motivation of this paper.

VATD models can be categorized into Lagrangian particle tracking and Eulerian advection-diffusion types. Among several available particle tracking models (e.g. Walko et al., 1995; Searcy et al., 1998; D'amours, 1998; Draxler and Hess, 1998) and advection-diffusion models (e.g. Bonadonna and Houghton, 2005; Folch et al., 2009; Schwaiger et al., 2012), we adopt a particle tracking model, Puff (Tanaka, 1991; Searcy et al., 1998), as the primary VATD model. Puff can accept a 3D point cloud description of the starting ash cloud as an initial condition, which makes it technically easier to couple with 3D plume models. Puff initializes a discrete number of tracers that represent a sample of the eruption cloud, and calculates transport, turbulent dispersion, and fallout for each representative tracer. A cylinder emanating vertically from the volcano summit to a specified maximum height is the standard approach to provide a simple model of the geometry of a typical ash column. Puff minimally requires horizontal wind field data. The “restart” feature of Puff makes it technically feasible to accommodate the hand-off between a plume simulation and the Puff simulation in terms of time and length scales.

We also implement one of the most widely used models for atmospheric trajectory and dispersion calculations, the Hybrid Single-Particle Lagrangian Integrated Trajectory model (HYSPLIT) (Stein et al.,

66 2015; Rolph et al., 2017), developed by NOAA's Air Resources Laboratory. HYSPLIT is able to simulate  
67 phenomena from simple back trajectories, to very sophisticated computations of transport, mixing, chemical  
68 transformation, and deposition of pollutants and hazardous materials. It is used in this study to better  
69 understand simulation results from Puff.

70 Besides parameter calibration, 1D plume models have been used to obtain global descriptors of volcanic  
71 plumes. 1D plume models (e.g. Woods, 1988; Bursik, 2001; Mastin, 2007; de'Michieli Vitturi et al., 2015;  
72 Folch et al., 2016; Pouget et al., 2016) solve the equations of motion in 1D using simplifying assumptions,  
73 and hence depend on estimation of certain parameters, especially those related to the entrainment of air,  
74 which is evaluated based on two coefficients: a coefficient due to turbulence in the rising buoyant jet, and  
75 one due to the crosswind field. Different 1D models adopt different entrainment coefficients based on a  
76 specific formulation or calibration against well-documented case studies. The feedback from plume to  
77 atmosphere is usually ignored in 1D models. While these 1D models generated well-matched results with  
78 3D models for plumes that are dominated by wind (often called weak plumes) much greater variability  
79 is observed for strong plume scenarios (Bursik et al., 2009; Costa et al., 2016). On the other hand, 3D  
80 numerical models for volcanic plumes based on first principles and having few parametrized coefficients  
81 (Oberhuber et al., 1998; Neri et al., 2003; Suzuki et al., 2005; Cerminara et al., 2016a; Cao et al., 2018)  
82 naturally create a 3D ash cloud, which could serve directly as an initial state of the volcanic material for  
83 VATDs. However, there is no VATD simulation using such 3D ash clouds as initial conditions. In this paper,  
84 we will carry out VATD simulations using an initial state for the ash cloud based on 3D plume simulations,  
85 generated with Plume-SPH (Cao et al., 2018, 2017). The implementation techniques described in this paper  
86 can be applied to any combination of VATD model and 3D plume model even though our investigation is  
87 based on a specific VATD model and plume model.

88 The 1991 eruption of Pinatubo volcano is used as a case study. Pinatubo erupted between June 12 and 16,  
89 1991, after weeks of precursory activity. The climactic phase started on June 15 at 0441 UTC and ended  
90 around 1341 UTC (Holasek et al., 1996a). The climactic phase generated voluminous pyroclastic flows,  
91 and sent Plinian and co-ignimbrite ash and gas columns to great altitudes (Scott et al., 1996). The evolution  
92 of the Pinatubo ash and  $SO_2$  clouds was tracked using visible (Holasek et al., 1996a), ultraviolet (Total  
93 Ozone Mapping Spectrometer; TOMS) (Guo et al., 2004a) and infrared sensors, including the Advanced  
94 Very High-Resolution Radiometer (AVHRR) (Guo et al., 2004b). There are sufficient observational data to  
95 estimate the eruption conditions for the climactic phase of the eruption (Suzuki and Koyaguchi, 2009). The  
96 availability of calibrated eruption conditions and extensive observational data regarding ash cloud transport  
97 make the Pinatubo eruption an ideal case study.

## 2 MATERIALS AND METHODS

### 2.1 Creation of Initial Ash Cloud

99 The steps to create an initial ash cloud based on the raw output of Plume-SPH are shown in Fig. 1.  
100 The method proposed consists in generating the initial ash cloud directly from Plume-SPH, foregoing  
101 assumptions and estimates, or inverse modeling, regarding ash injection height and timing. We use Plume-  
102 SPH as an example, noting that for other 3D plume models, the steps would be similar. Plume-SPH is a  
103 two-phase model based on the Lagrangian smoothed-particle hydrodynamics (SPH) method, in which the  
104 computational domain is discretized by SPH particles. The current version, Plume-SPH 1.0 (Cao et al.,  
105 2018), uses two types of SPH particles: 1) particles of phase 1 to represent ambient air, and 2) particles of  
106 phase 2 to represent erupted material. The initial ash cloud is created from SPH particles of phase 2.

107 After reaching the maximum rise height and starting to spread horizontally, particles of phase 2 form an  
 108 initial umbrella cloud (Fig. 2). The 3D plume simulation is considered complete once the umbrella cloud  
 109 begins to form. Parcels that will be transported by the ambient wind are those above the “corner” region,  
 110 where mean plume motion is horizontal rather than vertical.

111 Considering that SPH particles are only discretization points, each is assigned a grain size according to a  
 112 given total grain size distribution (TGSD) (Paladio-Melosantos et al., 1996), and a concentration according  
 113 to the mass and volumetric eruption rate. The Plume-SPH discretization points are thus switched to Puff  
 114 Lagrangian tracer particles having grain sizes and concentrations. The coordinates of these tracer particles,  
 115 which are initially in the local Cartesian coordinate system of Plume-SPH, are converted into Puff’s global  
 116 coordinate system, which is given in terms of (*longitude, latitude, height*). Puff takes the initial ash  
 117 cloud, consisting of the collection of Lagrangian tracer particles with grain size and concentration, and  
 118 propagates from time  $t$  to time  $t + \Delta t$  via solution to an advection/diffusion equation (Searcy et al., 1998):

$$\mathbf{R}_i(t + \Delta t) = \mathbf{R}_i(t) + \mathbf{W}(t)\Delta t + \mathbf{Z}(t)\Delta t + \mathbf{S}_i(t)\Delta t \quad (1)$$

120 Here,  $\mathbf{R}_i(t)$  is the position vector of the  $i^{th}$  Lagrangian tracer particle at time  $t$ ,  $\mathbf{W}$  accounts for wind  
 121 advection,  $\mathbf{Z}$  accounts for turbulent dispersion and  $\mathbf{S}$  is the terminal gravitational fallout velocity or settling  
 122 speed, which depends on a tracer’s size.

123 To summarize, there are four steps to create an initial ash cloud from the raw output of Plume-SPH:

- 124 1. filter by SPH particle type to select SPH particles that represent erupted material (phase 2)
- 125 2. filter by a mean velocity threshold to select the upper part (above the “corner” region) dominated by  
 126 horizontal transport
- 127 3. switch SPH discretization points to Lagrangian tracer particles, by assigning grain size to each particle
- 128 4. convert coordinates of the SPH Lagrangian tracers into the VATDs’ geographic coordinate system

129 The features of the volcanic plume and resulting initial ash cloud used in the case study are shown in Fig. 2.  
 130 It is important to point out that since both Plume-SPH and Puff are based on the Lagrangian method, there  
 131 is no extra step of conversion between an Eulerian grid and Lagrangian particles.

132 Table 1 compares three different methods for creating initial conditions for a VATD simulation: 1)  
 133 creating initial conditions based on parameter calibration without any plume model (method 1), 2) creating  
 134 initial conditions based on output of a 1D plume model (method 2), 3) extracting an initial ash cloud from  
 135 a 3D plume simulation (method 3). The first method determines all global descriptors of volcanic plumes  
 136 based on calibration. An initial line source or ash cloud is then created according to a semiempirical plume  
 137 shape expression. Both of the other two methods depend on plume models. However, 3D plume models  
 138 can generate initial ash clouds in 3D space, while 1D plume models only generate global descriptors of  
 139 a plume, so a semiempirical expression or transformation is still needed to create a 3D initial ash cloud.  
 140 In addition, the number of Lagrangian tracers is a free parameter when using semiempirical plume shape  
 141 expressions, while it depends on a computationally optimized simulation when generating them from the  
 142 output of a 3D plume simulation.

## 143 2.2 Puff Restart

144 The plume and ash transport models are run at different time scales and length scales. The spatial and  
 145 temporal resolutions of the plume simulations are much finer than those of the ash transport model. It takes  
 146 tens of minutes (600s in this case) for the Pinatubo plume to reach a steady height. However the eruption

147 persisted for a few hours (9 hours for the climactic phase of Pinatubo eruption), and it may be necessary  
148 to track ash transport for days following an eruption. At present, it is too expensive computationally to  
149 do 3D plume simulations of several hours in real time. In order to handle the difference in time scale, we  
150 mimic a continuing eruption with intermittent pulses releasing ash particles. In particular, we restart Puff at  
151 an interval of 600s, i.e., the physical time of the plume simulation to reach a steady height. At every Puff  
152 restart, we integrate the output of the last Puff simulation and Plume-SPH into a new ash cloud. This new  
153 ash cloud serves as a new initial condition with which to restart a Puff simulation. A sketch demonstrating  
154 the overall restart process is shown in Fig. (3). The total number of Lagrangian tracer particles used in Puff  
155 thus equals the summed number of particles in all releases. The total number of tracer particles is therefore  
156 no longer a user-selected parameter. Fero et al. (2008) proposed using more realistic time-dependent plume  
157 heights. We do not adopt that strategy here for simplicity, although the idea would be straightforward in  
158 execution, given time-dependent eruption conditions.

### 159 2.3 Sensitivity Analysis of Other Parameters

160 Besides the positions of particles in the initial ash cloud, other parameters for Puff simulations are:  
161 horizontal diffusivity, vertical diffusivity, mean grain size, grain size standard deviation and total number  
162 of tracers. We present in this subsection informal but systematic sensitivity studies on these parameters.  
163 We also investigate the influence of eruption duration. The sensitivity analyses will serve as the basis for  
164 identifying possible sources of disparities between simulation and observation.

165 The sensitivity analyses illustrate that adjustment of parameters other than the positions of particles in  
166 the initial ash cloud produces negligible visual differences in VATD simulation results. Using horizontal  
167 diffusivities in the range of  $[100, 100000] m^2 s^{-1}$  and vertical diffusivities in the range of  $[1, 20] m^2 s^{-1}$   
168 produces visually negligible differences. The simulated eruption duration should depend on either the  
169 total observed duration or the duration of the climactic phase. We conducted several simulations with  
170 eruption duration varying in the range of  $[5, 11] hours$  with slightly different starting time of climactic  
171 phase. Table 2 lists all these simulations. However, only slight visible differences are observed among the  
172 simulated ash transport outputs. The mean of the grain size distribution also has visually negligible effects  
173 on long-term ash transport, according to our sensitivity tests in which we varied the log mean (base 10)  
174 grain radius in the range of  $[-7.3, -3.5] m$ . The standard deviation, when varying in the range of  $[0.1, 10]$   
175  $m$ , generates a negligible difference on long-range ash transport as well. A similar conclusion on parameter  
176 sensitivity is reported by Fero et al. (e.g. 2008); Daniele et al. (e.g. 2009). Among the parameters explored,  
177 the eruption duration and beginning time show the most obvious influence on simulated ash distribution,  
178 although the effect is still small. To show the differences in an intuitive way, Fig. ?? shows simulated  
179 ash distribution corresponding to 4.9 hours duration, 9 hours duration and 11 hours duration, respectively.  
180 After 72 hours, relative to the simulation starting time, these three cases generate generally similar results,  
181 with high concentration ash covering almost the same region. Ash cloud covers the broadest area when the  
182 eruption duration is 11.1 hours. To summarize, all these parameters have negligible effects on long-term  
183 ash distribution.

184 The new methodology for generating initial ash clouds introduces a new parameter: elevation threshold,  
185 which is the lower elevation limit of the ash that will be transported by the VATD. This parameter needs to be  
186 specified at this time, as there is no *a priori* way to define it, given the continuous vertical distribution of ash  
187 in the eruption column. We carry out a separate, informal sensitivity analysis on this parameter by varying  
188 the elevation threshold from 1500 m (the height of the vent) to 25000 m. The simulated ash distributions  
189 show obvious visible differences. Such influence is especially obvious when the elevation threshold is  
190 either very high or very low. However, varying the elevation threshold in the range of  $[12000, 18000] m$

generates relatively small differences in ash transport simulation results. Figure 4(d) and (e) compare the simulated ash distributions corresponding to elevation thresholds of 1500 m and 15000 m. Compared with the ash distribution for a threshold of 15000 m, an extra long tail appears when using an elevation threshold of 1500 m. Adopting lower elevation thresholds adds more tracer particles at lower elevation. As the winds at different elevations are different, the tracers at lower elevations propagate in different directions. The HYSPLIT (Stein et al., 2015; Rolph et al., 2017) forward trajectory tracking starting at 1624 UTC on June 15, indicates that the wind between elevations of 10000 m and 15000 m blew from north-east to south-west, while winds of higher elevation blew from east to west (see Fig. 5). The results suggest that the elevation threshold is best estimated from the height at which the parcel number or mass concentration has an inflection point in the vertical distribution (*cf.* Figure 4(a) and (b)). Below this inflection point, particle trajectories are primarily vertical in the stalk-like eruption column. Above this level, particle trajectories are primarily horizontal, as they flow into the umbrella cloud gravity current.

The sensitivity analyses demonstrate that the initial conditions for the VATD simulations, derived from the plume model, have the most significant effect on simulated ash propagation, while all other input parameters have negligible influence. An initial ash cloud generated based on the semiempirical expression, which is a function of several parameters, often differs significantly from a realistic ash cloud. Such initial conditions might greatly compromise the accuracy of a VATD simulation.

In this paper, we do not carry out any sensitivity investigation with respect to wind field, even though it is a dominant factor in a VATD simulation. In the present case study, we use global NOAA/OAR/ESRL6–*h*, 2.0° reanalysis wind field data (Whitaker et al., 2004; Compo et al., 2006, 2011).

### 3 RESULTS

Transport of volcanic ash resulting from the Pinatubo eruption on June 15, 1991, is simulated using two different initial conditions. The first type of initial condition is created in a traditional way according to key global descriptors and the semiempirical plume shape expression. The second type of initial condition is created by the new method proposed in this paper. Simulated ash transport results are compared against observations.

To create initial conditions using the new method described in this paper, the plume rise is simulated first by Plume-SPH. The eruption parameters, material properties and atmosphere for the “Strong plume–no wind” case in the recent comparison study on eruptive column models (Costa et al., 2016) are adopted. Eruption conditions and material properties are listed in Table 3. Note that the density of erupted material at the vent and radius of the vent can be computed from the given parameters. The eruption pressure is assumed to be the same as the atmospheric pressure at the vent, hence is not given in the table. The vertical profiles of atmospheric properties were based on the reanalysis data from ECMWF (European Centre for Medium-Range Weather Forecasts) for the period corresponding to the climactic phase of the Pinatubo eruption. The initial ash cloud is obtained by processing the raw output of Plume-SPH following steps described in Sec. 2.

Another set of initial conditions from semiempirical plume shape is created using the observed initial top height (40km) and several other parameters assigned semiempirically (Bursik et al., 2012). These parameters, namely, the global descriptors of the volcanic plume, are used as parameters in a semiempirical expression to obtain an ash cloud in 3D space (Table 4). Except for initial conditions, the simulation parameters that control the VATD simulation are the same for both simulations. As has been shown in the sensitivity analysis section, these parameters have less influence on simulation results than do initial conditions.

The simulation results using different initial conditions are compared with TOMS images and AVHRR BTD ash cloud map imagery (Fig. 6). The differences between simulated ash transport by the “Semiempirical initial cloud +Puff” and “Plume-SPH+Puff” conditions are significant. The simulated ash concentration based on the initial conditions created from Plume-SPH is qualitatively closer to observation than that based on the semiempirical plume shape expression. At 23 hours and 31 hours after the beginning of the climactic phase, the “Plume-SPH + Puff” simulation generates ash footprints that are closer to observations, especially in forecasting the location where there is a high concentration of ash. However, ash just west of Pinatubo observed in satellite images does not show up in “Plume-SPH + Puff” simulation results. This disparity is likely due to the fact that Pinatubo continued erupting after the climactic phase, while we only simulate the climactic phase. The “Semiempirical initial cloud + Puff” simulation, however, forecasts an ash distribution more spatially restricted than observation. The location of the high concentration region is far northwest of observation. Around 55 hours after the beginning of the climactic phase, the disparity between observation and simulation becomes more obvious. Ash in the “Semiempirical initial cloud + Puff” simulation is located too far west of the observation. The high concentration area of the “Plume-SPH + Puff” simulation, even though closer to observation than that of the “Semiempirical initial cloud +Puff” simulation, has also propagated further than observation.

Except for the initial conditions, both simulations adopt the same parameters and wind field data. That is to say, the only difference between these two simulations is the initial distribution of ash parcels. The main difference between simulation results from the “Plume-SPH+Puff” and the “Semiempirical initial cloud +Puff” runs can be directly attributed to the initial ash particle distribution, which we discuss in detail in the following section.

## 4 DISCUSSION

### 4.1 Importance of Maximum Height ( $H_{max}$ )

In this section, we discuss the vertical distribution of ash particles in the initial ash cloud. The majority of volcanic ash particles are usually injected at an elevation lower than the maximum height. For instance, Holasek et al. (1996a,b) reported the maximum Pinatubo plume height as  $\sim 39\text{ km}$  while the cloud heights were estimated at  $\sim 20 - 25\text{ km}$ . Self et al. (1996) reported that the maximum plume height could have been  $> 35\text{ km}$ , but that plume heights were  $23 \sim 28\text{ km}$  after  $\sim 15 - 16\text{ hours}$ . The neutral buoyancy height of the Pinatubo aerosol cloud was estimated with different methods at:  $\sim 17 - 26\text{ km}$  (lidar) by DeFoor et al. (1992),  $\sim 20 - 23\text{ km}$  (balloon) by Deshler et al. (1992),  $\sim 17 - 28\text{ km}$  (lidar) by Jäger (1992), and  $\sim 17 - 25\text{ km}$  (lidar) by Avdyushin et al. (1993). Based on comparison between simulated clouds with early infrared satellite imagery of Pinatubo, Fero et al. (2008) reported that the majority of ash was transported between  $16\text{ km}$  and  $18\text{ km}$ . These observations make good physical sense, as particles are concentrated near the intrusion height of the umbrella cloud, not near the plume top, because the plume top is due to momentum overshoot. However, the empirical expressions for the height-MER relation, which are commonly adopted to create initial conditions for VATD simulations, tend to place the majority of ash particles closer to the top if one uses observed maximum height in the empirical expressions.

Here we investigate two commonly used plume shapes, the Poisson and Suzuki. For the Poisson plume shape, the vertical height of ash particles is given by Eq. (2):

$$H = H_{max} - 0.5H_{width} * P + H_{width}R \quad (2)$$

where  $P$  is an integral value drawn from a Poisson distribution of unit mean,  $R$  is a uniformly distributed random number between 0 and 1,  $H_{max}$  is the maximum plume height,  $H_{width}$  represents an approximate

273 vertical range over which the ash will be distributed. For the Suzuki plume shape (Suzuki et al., 1983), the  
 274 ash mass vertical distribution is assumed to follow the equation (Eq. (3)):

$$Q(z) = Q_m * \frac{k^2(1 - z/H_{max})\exp(k(z/H_{max} - 1))}{H_{max} [1 - (1 + k)\exp(-k)]} \quad (3)$$

275 Where  $Q_m$  is the total mass of erupted material,  $k$  is shape factor, which is an adjustable constant that  
 276 controls ash distribution with height. A low value of  $k$  gives a roughly uniform distribution of mass with  
 277 elevation, while high values of  $k$  concentrate mass near the plume top.

278 Particle distributions (in terms of mass percentage or particle number percentage) in the vertical direction  
 279 in the initial ash cloud are shown in Fig. 7. In that figure, the vertical particle distribution based on  
 280 Plume-SPH output is compared with the vertical particle distribution created based on semiempirical shape  
 281 expressions. Both Poisson and Suzuki distributions in Fig. 7 take  $H_{max} = 40$  km, which is close to the  
 282 reported observation of maximum height. When adopting the Poisson distribution, the majority of the  
 283 particles are between  $30\text{km} \sim 40\text{km}$ . Obviously, the Poisson function distributes the majority of ash at a  
 284 higher elevation than was observed (e.g. Fero et al., 2008). As for the Suzuki distribution, the majority  
 285 of ash particles also occur in a range that is significantly higher than 25 km. As for initial ash clouds  
 286 based on Plume-SPH simulation, most ash particles are distributed between  $\sim 17 - 28$  km, which matches  
 287 well with observations. The maximum height is also consistent with observation. To summarize, using a  
 288 semiempirical plume shape expression generates an unrealistic initial ash cloud even if we use the observed  
 289 maximum plume height.

290 For the Poisson and Suzuki distributions, the maximum in ash particles cannot be lower without changing  
 291 the maximum height. To distribute the majority of ash particles at a lower elevation, the maximum height  
 292 must be reduced to a value smaller than the observed maximum height. Adjusting parameters such as  
 293 maximum height in the empirical expression is actually the traditional source term calibration method. A  
 294 set of initial ash clouds using different maximum heights based on the Poisson distribution is shown in Fig.  
 295 8). The maximum heights adopted in plume shape expressions are not obtained from any plume model or  
 296 observation of plume height, but by *a posteriori* calibration to later-observed ash cloud transport heights.

297 The ash clouds created by the Poisson distribution with different maximum heights are used as initial  
 298 conditions in Puff simulations, whose results are shown in Fig. 11. Except for the maximum height, all  
 299 other parameters for creating an initial ash cloud are the same as those in Table 4. Of course, the range  
 300 over which the majority of ash particles is located is lower when using lower maximum heights. Figure  
 301 11 thus shows that the maximum height has a significant influence on the ash transport simulation. When  
 302 the maximum height is 10 km, the high concentration area lags behind that observed. If the designated  
 303 maximum height is 35 km, the high concentration area propagates faster and is more spatially confined  
 304 than observed. When using a maximum height of  $\sim 41000$  m, the high concentration area propagates faster  
 305 and the footprint is narrower than in both observation and “Plume-SPH+Puff” simulation results (see Fig. 6).  
 306 The simulated high concentration area is closest to “Plume-SPH+Puff” simulation results when assigning a  
 307 maximum height of 30 km. The low-concentration front of the volcanic ash cloud propagates faster than  
 308 observed, and is located far west of the high concentration areas. A low concentration tail area also appears  
 309 in the simulation results while there is no such tail in the observed imagery, although this could be the  
 310 result of imagery calibration or sensitivity. Simulation results based on a calibrated maximum height of 30  
 311 km show a footprint similar to those of “Plume-SPH+Puff”, although smaller in terms of area. However,  
 312 the initial ash cloud created by a Poisson distribution with maximum height around 20 km generates the  
 313 best match ash with observation. That is to say, a maximum height lower than the real maximum height

is required by the Poisson plume shape to distribute ash particles at elevations comparable to the “true” ash distribution. Our hypothesis regarding the disparity between the “Semiempirical initial cloud +Puff” simulations and observation is confirmed. Since the initial condition of vertical ash distribution has such a dominant effect on VATD simulation, it is critical for the forecast capability of VATD simulations to explore more accurate and adaptive ways for establishing the initial ash distribution, especially methods that do not rely on *a posteriori* parameter calibration or inversion.

## 4.2 Effect of Vertical Spread ( $H_{width}$ )

In the previous section, we explored the effects of adjusting the maximum height to change the vertical ash distribution at the source. In this section, we investigate the importance of another parameter in the semiempirical Poisson expression. We vary the “vertical spread” ( $H_{width}$  in Puff) in the range  $\sim 3 - 10$  km. A set of initial ash clouds with different vertical spreads are shown in Fig. 8. Except for vertical spread, all other parameters for creating an initial ash cloud are the same as those in Table 4. The vertical width of the region within which the majority of ash particles are located becomes narrower when a smaller value for the vertical spread parameter is used, but changing it has no obvious effect on the height at which the largest fraction of ash particles is injected (essentially the height of a mode in ash distribution). The ash clouds based on different vertical spread parameters are then used as initial conditions in Puff simulations.

The results are shown in Fig. 11. Adjusting of the vertical spread changes particle distribution in the vertical direction, and thus, not surprisingly affects the VATD simulation results. None of the VATD simulations based on initial ash clouds with vertical spreads equal to 3, 5 or 10 km yield better results than do VATD simulations based on initial conditions created by Plume-SPH (see Fig. 11).

The calibration tests on vertical spread, carried out here, are certainly not exhaustive. One could do a more comprehensive calibration throughout the multi-dimensional parameter space (for Poisson distribution, the parameter space is two dimensional) and find better results. In addition, with a more complicated semiempirical plume shape expression, one could have more control over plume shape and might be able to get an initial condition that yields more accurate ash transport forecast. However, more complicated and adaptable plume shape expressions imply a higher dimensional parameter space, which requires more effort in calibration, even though the degrees of freedom to adjust plume shape are still limited. Creating initial conditions based on 3D plume simulations is more adaptive to various cases and yields results as good as or better than calibration of the poorly-constrained semi-empirical parameter, vertical spread.

## 4.3 Horizontal Ash Distribution

The differences between the semiempirical plume particle distribution and actual (or simulated by the 3D plume model) are not only in the vertical direction. The importance of the horizontal distance of each initial ash particle from a line extending upward from the volcano is investigated in this section. Puff uses a uniformly distributed random process to determine ash particle locations in a circle centered on the volcano site. The maximum radius (at plume top) at which a particle can be located is given as “horizontal spread” (Table 4). The horizontal displacement from a vertical line above the volcano is a random value within a circle of which the radius equals the “horizontal spread” multiplied by the ratio of the particle height  $H$  to the maximum  $H_{max}$ . So the resulting shape of the particle distribution within the plume is an inverted cone in which particles are located directly over the volcano at the lowest level and extend out further horizontally with increasing plume height. For the output of Plume-SPH, an effective (maximum) radius is determined according to a given threshold of ash concentration, following Cerminara et al. (2016b). A time averaged, spatial integration of the dynamic 3D flow field is conducted to remove significant fluctuations in time and space. Fig. 9 compares radius of the initial ash clouds created by 3D plume simulations with that assumed in the semiempirical plume shape expression adopted in Puff. It is impossible for the

358 simple, assumed plume shapes to capture the complex and more realistic shapes developed by Plume-SPH.  
359 Additional parameterization may generate more reasonable shapes, but these would continue to be *ad hoc*,  
360 none would likely to have the potential fidelity of the 3D simulation to reality, and adding a temporally  
361 changing distribution would be difficult.

362 Comparison between cross-sectional views of the initial ash clouds is shown in Fig. 10. The cross-  
363 sectional view of horizontal particle distribution using the semiempirical method (last figure in Fig. 10)  
364 is similar to a cross-sectional view of a simulated 3D plume, in a general sense. However, for simulated  
365 3D plumes, the ash particle distribution in cross section varies with height, which factor would become  
366 increasingly important with increasing wind speed, were wind speed to be included in the estimate of initial  
367 plume shape. It is difficult for the semiempirical expressions to accommodate such a complex distribution.

368 Despite the obvious difficulty of correctly estimating ash distribution near the vent, or for short propagation  
369 times, assigning different values for the horizontal spread has a negligible effect on VATD simulation  
370 results at large time. We investigated horizontal spread values between 50 km and 1600 km as to create  
371 initial ash clouds; all of them generated similar results at large propagation times ( $> 1$  day). Figure 11  
372 shows two different simulation results based on initial ash clouds with horizontal spread equal to 50 km  
373 and 600 km, respectively. No visible differences are apparent between them. This implies that horizontal  
374 distribution has a less significant influence on VATD simulation results than does vertical distribution for  
375 long distance or large time. Perhaps the most important ramification of this result is that it means the time  
376 at which the “handshake” is made between Plume-SPH and the VATD does not affect results significantly  
377 for relatively large distances and times.

#### 378 4.4 Summary

379 This paper presents, for the first time, VATD simulations using initial source conditions created by a 3D  
380 plume model. Traditional VATD simulations use initial conditions created according to a semiempirical  
381 plume shape expression. A case study of the 1991 Pinatubo eruption demonstrates that a 3D plume model  
382 can create more realistic initial ash cloud and ash parcel positions, and therefore improve the accuracy of  
383 ash transport forecasts. Informal sensitivity analyses suggest that initial conditions, as expressed in the  
384 disposition of initial ash parcel positions in the vertical, have a more significant effect on a volcanic ash  
385 transport forecast than most other parameters. Comparison of initial ash parcel distributions among the  
386 3D plume model, semiempirical expressions, and observations suggests that a major subpopulation of ash  
387 parcels should be placed at a much lower elevation than maximum height to obtain a better VATD forecast.  
388 For the Pinatubo case study, “well-matched” simulation results are observed when using a maximum height  
389 of around 30km in semiempirical expressions, which is much lower than the observed maximum height of  
390 40km. Comparing the effects of the maximum height, vertical spread and horizontal spread shows that ash  
391 particle distribution in the vertical direction has the strongest effect on VATD simulation.

392 To summarize, we have presented a novel method for creating *a priori* initial source conditions for  
393 VATD simulations. We have shown that it might be possible to obtain initial positions of ash parcels  
394 with deterministic forward modeling of the volcanic plume, potentially obviating or lessening the need to  
395 attempt to somehow observe initial positions, or *a posteriori* create a history of release heights via inversion  
396 (Stohl et al., 2011). Although the method now suffers from the high computational cost associated with  
397 3D forward modeling, there is the possibility that in future it might not only help overcome shortcomings  
398 of existing methods used to generate *a priori* input parameters, but also overcome the need to do the  
399 thousands of runs associated with inverse modeling. In addition, computational cost will continue to  
400 diminish as computing speed increases. As they are forward numerical models based on first principles,  
401 3D plume models need little if any parameterization, and user intervention should not be required to

402 improve forecast power; no assumption about the initial position of ash parcels is needed. Generation of the  
403 initial cloud of ash parcels directly by 3D simulation is potentially adaptable to a variety of volcanic and  
404 atmospheric scenarios. In contrast, semiempirical expressions used to determine initial conditions require  
405 several parameters to control ash particle distribution along a vertical line source or some simplified shape  
406 of the initial ash cloud, making it difficult in some cases to generate initial conditions that closely resemble  
407 a complex reality.

408 The full range of research issues raised by numerical forecasting of volcanic clouds is diverse. We  
409 described in this paper the effect of initial conditions chosen from the output of a 3D plume model on  
410 numerical forecasts of volcanic ash transport simulations. The wind field, another important factor in  
411 volcanic ash transport simulations, is not discussed in the present work. Some other aspects, such as  
412 microphysical processes, even though they play lesser roles, likely need to be included in VATDs to  
413 improve accuracy for a particular eruption. In addition, eruption conditions are subject to change with time,  
414 even during the climactic phase of an eruption. In the future, time-dependent initial conditions for VATDs  
415 can be created from 3D plume simulations with time-dependent eruption conditions.

## CONFLICT OF INTEREST STATEMENT

416 The authors declare that the research was conducted in the absence of any commercial or financial  
417 relationships that could be construed as a potential conflict of interest.

## AUTHOR CONTRIBUTIONS

418 The idea of using 3D plume model to start a VATD simulation originated from a conservation between AP  
419 and MB. ZC carried out the Plume-SPH simulations, PUFF simulations, results analysis, and prepared the  
420 first draft. All authors worked together for further revisions. MB carried out the HYSPLIT simulation. QY  
421 post processed the PUFF simulation results, overlapped the simulation results with satellite observation.  
422 All authors contributed equally to the manuscript writing. AP and MB got fundings to financially support  
423 the work.

## FUNDING

424 Details of all funding sources should be provided, including grant numbers if applicable. Please ensure to  
425 add all necessary funding information, as after publication this is no longer possible.

## ACKNOWLEDGMENTS

426 Support for the Twentieth Century Reanalysis Project dataset is provided by the U.S. Department of Energy,  
427 Office of Science Innovative and Novel Computational Impact on Theory and Experiment (DOE INCITE)  
428 program, and Office of Biological and Environmental Research (BER), and by the National Oceanic and  
429 Atmospheric Administration Climate Program Office.

## FIGURE CAPTIONS

**Table 2.** The starting and ending time (UT) for simulating the climactic phase of Pinatubo eruption on June 15 1991. Observed plume height (Holasek et al., 1996a) at different time are also listed in the table.

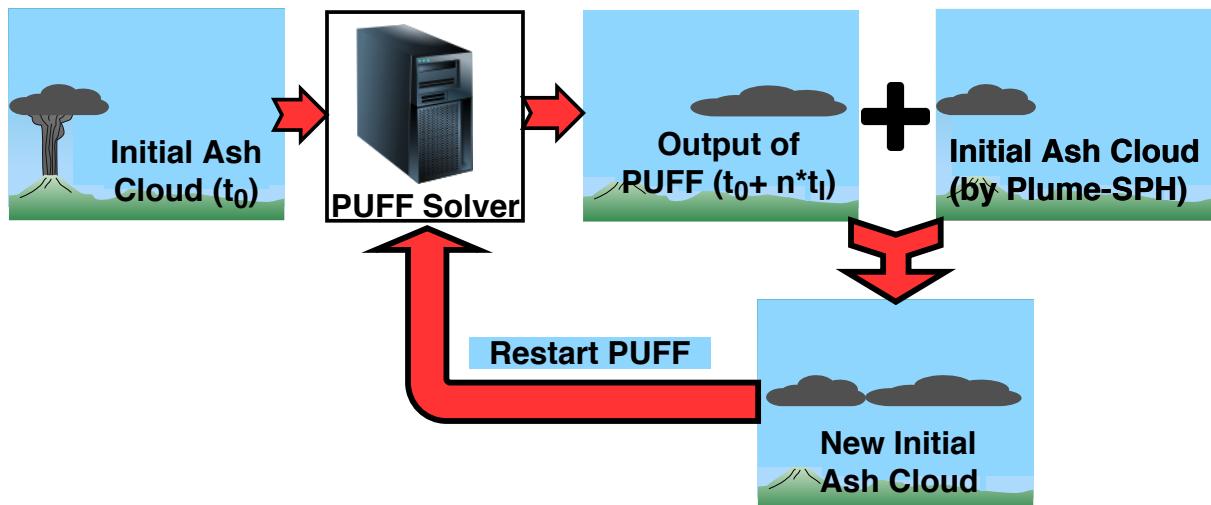

Eruption duration	4.9 hours	9 hours	10 hours	11.1 hours
Start time	0441	0441	0441	0334
Height at start time	37.5 km	37.5 km	37.5 km	24.5 km
End time	0934	1341	1441	1441
Height at end time	35 km	26.5 km	22.5	22.5 km

**Figure 1.** Steps to create initial condition for Puff based on raw output of Plume-SPH (Cao et al., 2018). First row: raw output of Plume-SPH. Blue particles are phase 1 (ambient air), red particles are phase 2 (erupted material). Second row: plume after removing SPH particles of phase 1. Picuture at right is colored according to mass fraction of erupted material. Third row: volcanic plume above the “corner” region after cutting off the lower portion. Forth row: assign sizes to particles converting numerical discretization points into tracers. Fifth row: switch coordinates in local coordinate system into (*longitude, latitude, height*)

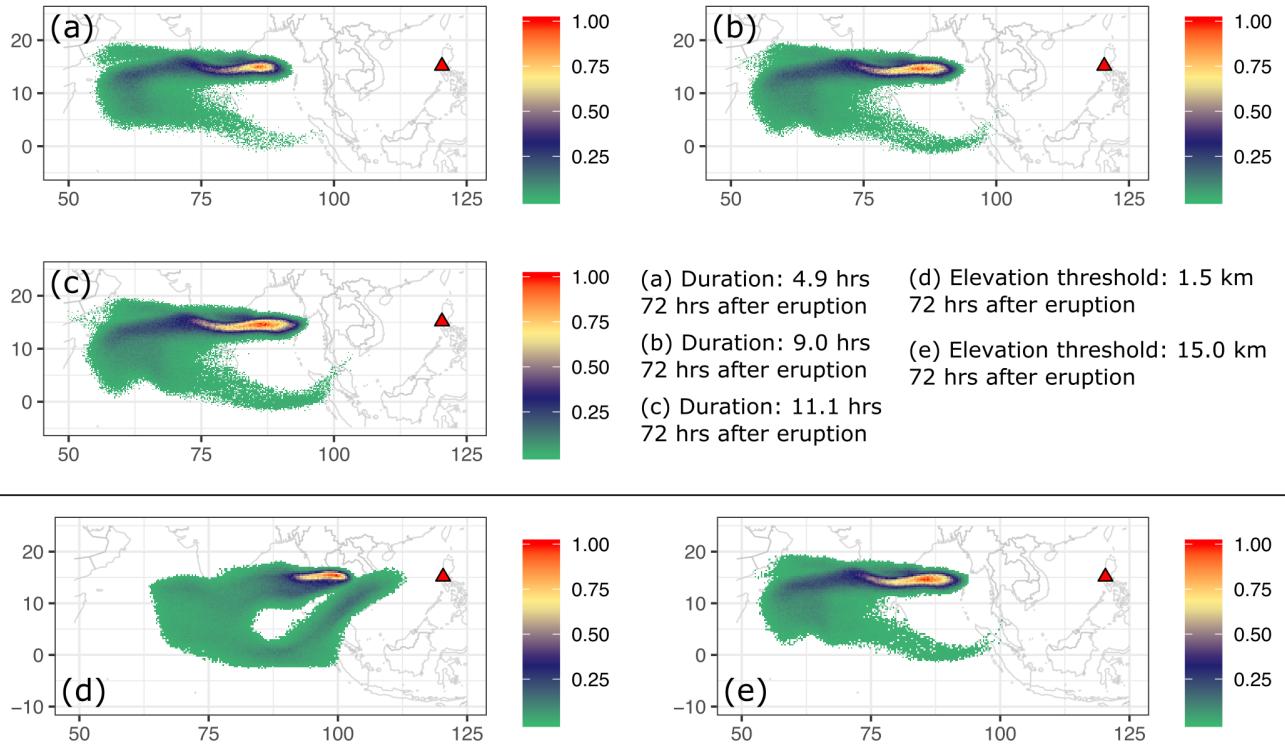

**Figure 2.** Volcano plume from 3D plume model. All particles in the pictures are of phase 2 (particle of phase 1 has been removed) at 600s after eruption, at which time, the plume has already reached the maximum height and started spreading radially. (a) is front view of the whole plume. (b) top view of the plume. (c) is front view of the initial ash cloud, which is essentially a portion of the whole plume with elevation higher than a given threshold (in this picture is 15000m). Particles are colored according to mass fraction of erupted material. Red represents high mass fraction while blue represents low mass fraction.

**Figure 3.** Mimic successive eruption with intermittent pulsed releasing of ash particles.  $t_I$  is the period of pulsing release.  $t_I$  equals the physical time of 3D plume simulation.

**Table 3.** List of eruption condition and material properties for plume simulation

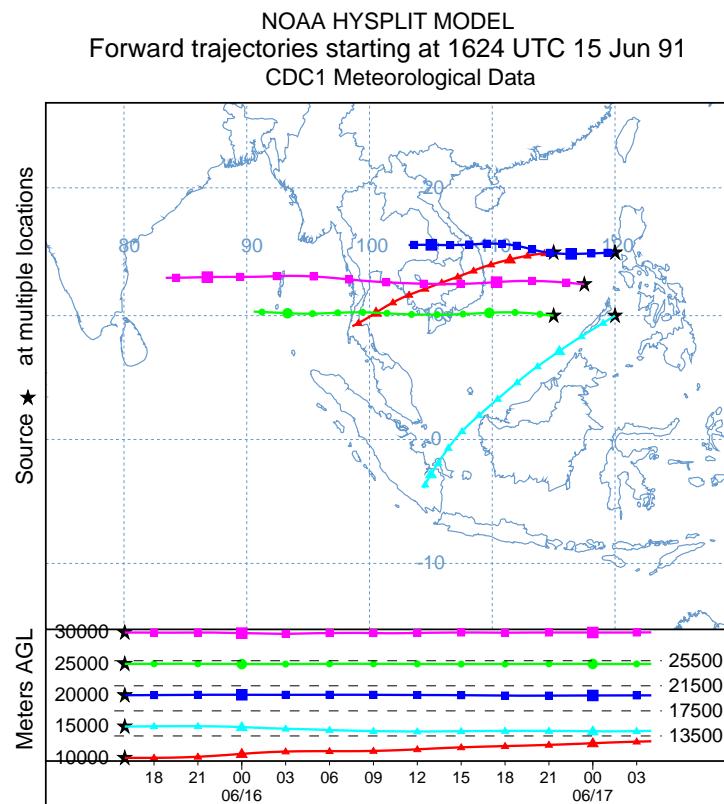

Parameters	Units	Plume
Vent velocity	$m \cdot s^{-1}$	275
Vent gas mass fraction		0.05
Vent Temperature	$K$	1053
Vent height	$m$	1500
Mass discharge rate	$kg \cdot s^{-1}$	$1.5 \times 10^9$
Specific heat of gas at constant volume	$J \cdot kg^{-1} \cdot K^{-1}$	717
Specific heat of air at constant volume	$J \cdot kg^{-1} \cdot K^{-1}$	1340
Specific heat of solid	$J \cdot kg^{-1} \cdot K^{-1}$	1100
Specific heat of gas at constant pressure	$J \cdot kg^{-1} \cdot K^{-1}$	1000
Specific heat of air at constant pressure	$J \cdot kg^{-1} \cdot K^{-1}$	1810
Density of air at vent height	$kg \cdot m^{-3}$	1.104
Pressure at vent height	$Pa$	84363.4

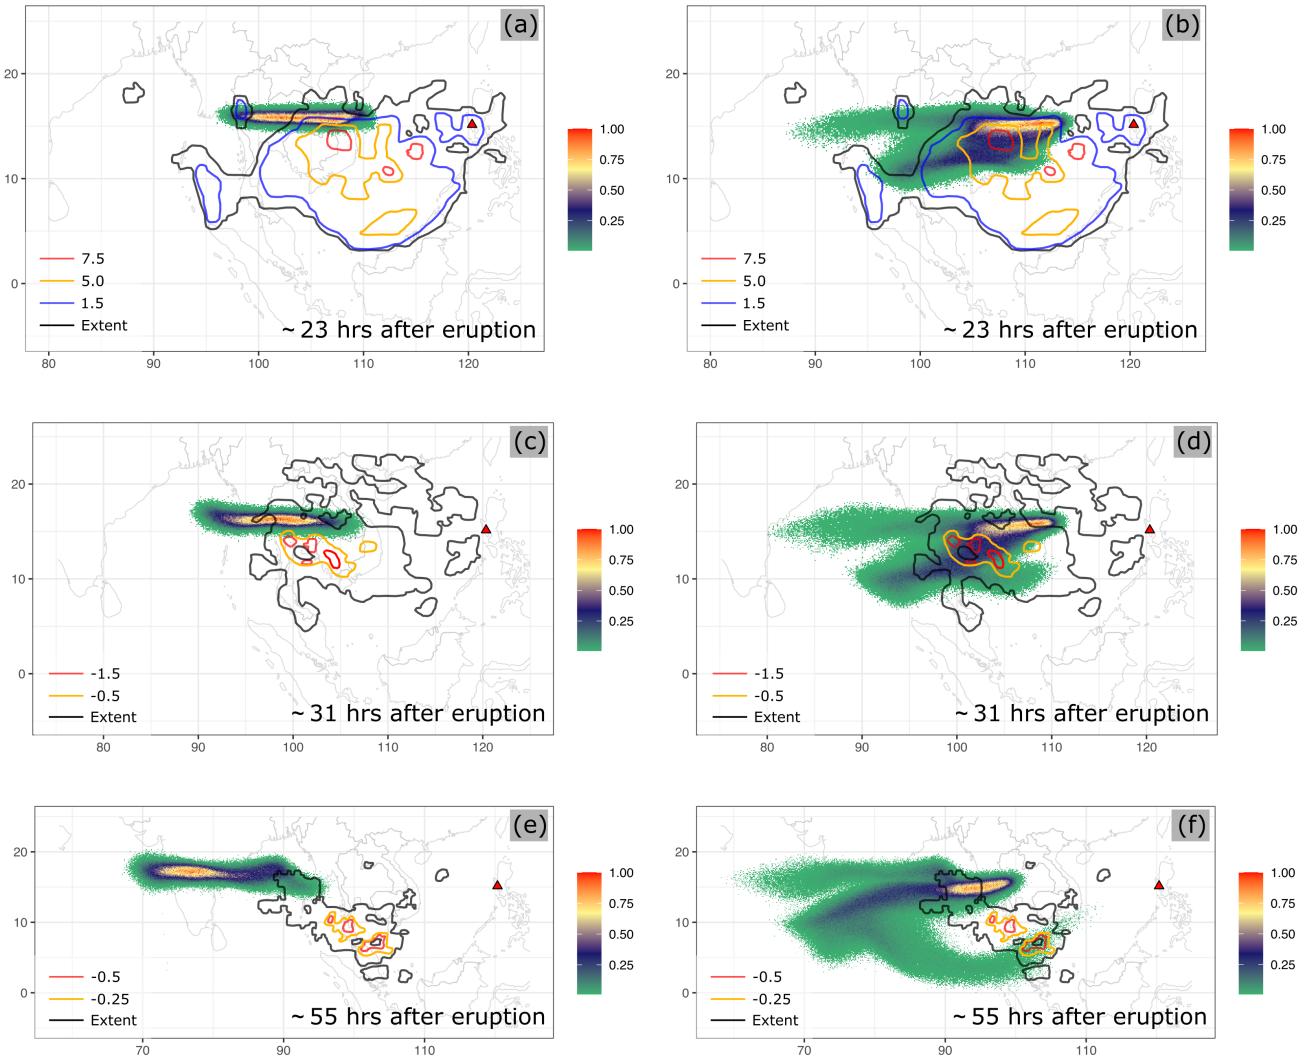

**Figure 4.** Sensitivity of Puff simulation with respect to eruption durations and initial ash cloud cutoff heights .(a) to (c) are simulated ash distribution with different starting and ending time. They corresponding to eruption duration of 4.9 hours, 9 hours and 11.1 hours respectively. Starting and ending time for each case is in Table 2. (d) and (e) are simulated ash distribution taking initial ash clouds obtained using different elevation thresholds (1500m and 15000 m) from output of Plume-SPH. The starting and ending time are corresponding to 9 hours duration case in Table 2. The contours correspond to ash concentration at 72 hours after eruption.

**Table 4.** Parameters used in VATD simulation of the climactic phase of Pinatubo eruption on June 15 1991. The first six parameters are used by semiempirical expression to create an initial ash cloud. When creating an initial condition based on the Plume-SPH model, these parameters are extracted from output of Plume-SPH model.

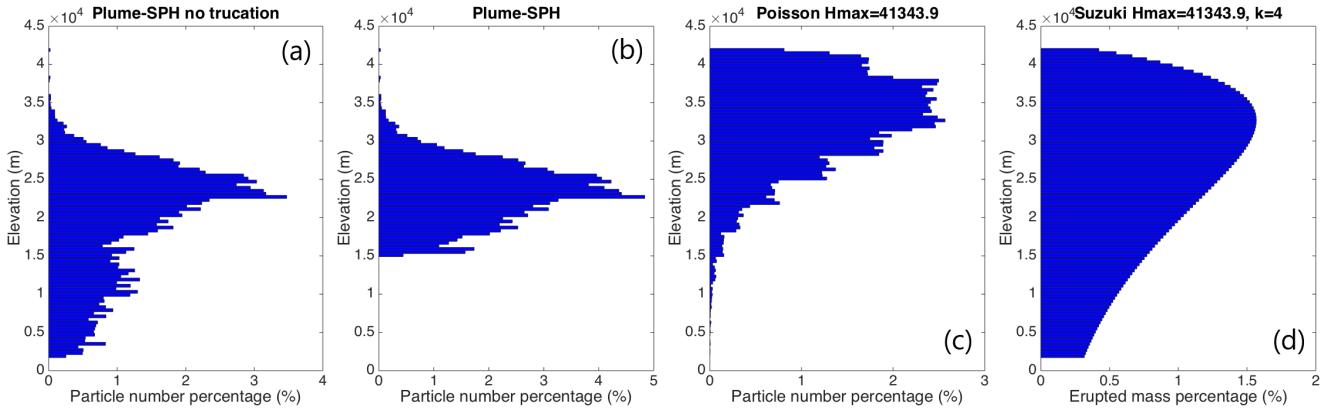

Parameters	Unit	Semiempirical	Plume-SPH
Maximum Height ( $H_{max}$ )	m	40000	41800
Horizontal Spread ( $R_{max}$ )	km	103.808	-
Vertical Spread ( $H_{width}$ )	km	6.662	-
Plume Shape	-	Poisson	-
Total Ash Particles	-	1768500	1768500
Elevation Threshold	m	-	15000
Horizontal Diffusivity	$m^2/s$	10000	10000
Vertical Diffusivity	$m^2/s$	10	10
Grain Size Distribution	-	Gaussian	Gaussian
Mean of Grain Size (Radius)	mm	$3.5 \times 10^{-2}$	$3.5 \times 10^{-2}$
Standard Deviation of Grain Size	-	1.0	1.0
Start Time	UT	0441	0441
End time	UT	1341	1341
Simulation Duration	hour	72	72

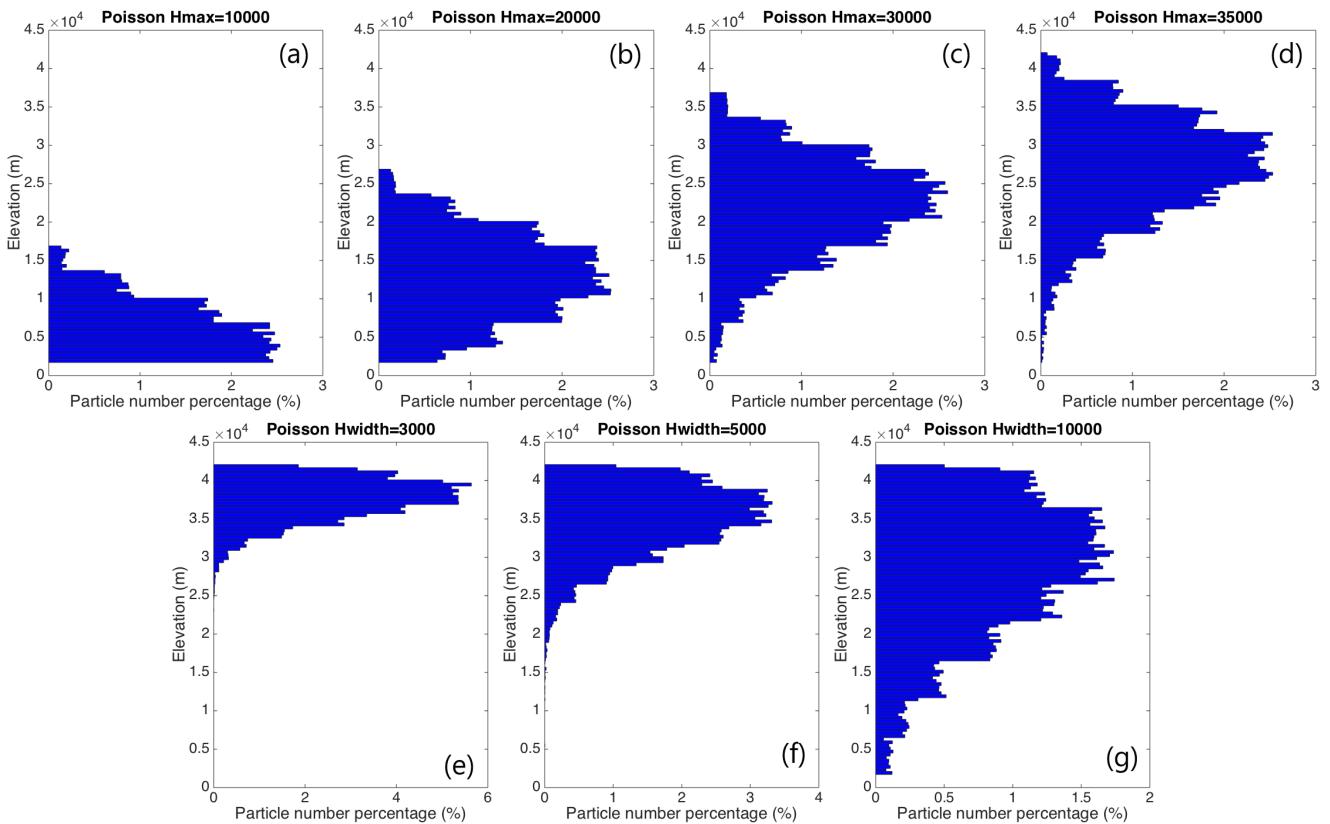

**Figure 5.** Trajectories of particles starting from different heights indicating the wind directions of different evaluations.

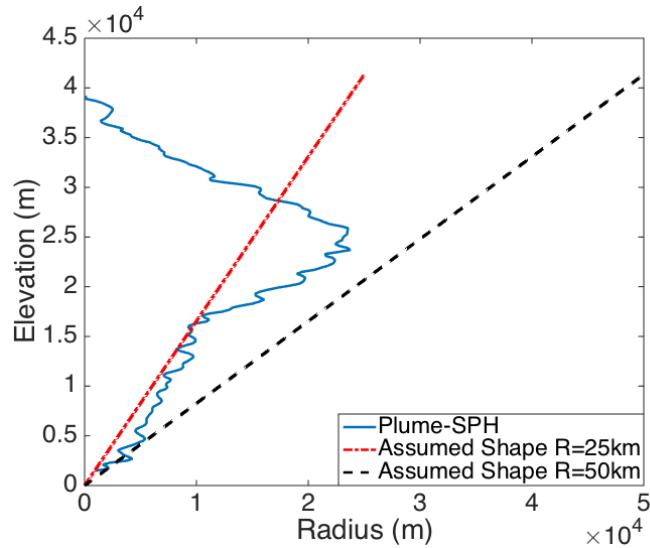

**Figure 6.** Comparison between “Semiempirical initial cloud + Puff” and “Plume-SPH + Puff”. Pictures to the left are: Puff simulation based on initial condition created according to semiempirical plume shape expression. Pictures to the right are Puff simulation based on initial condition generated by Plume-SPH. TOMS or AVHRR image of Pinatubo ash cloud are overlapped with the simulation results. Ash clouds at different hours after eruption are on different rows. From top to bottom, the images are corresponding to around 23 hours after eruption (UT 199106160341), 31 hours after eruption (UT 199106161141), 55 hours after eruption (UT 199106171141). The observation data on the first row are TOMS ash and ice map. The observation data on the second and third row are AVHRR BTD ash cloud map with atmospheric correction method applied (Guo et al., 2004b).

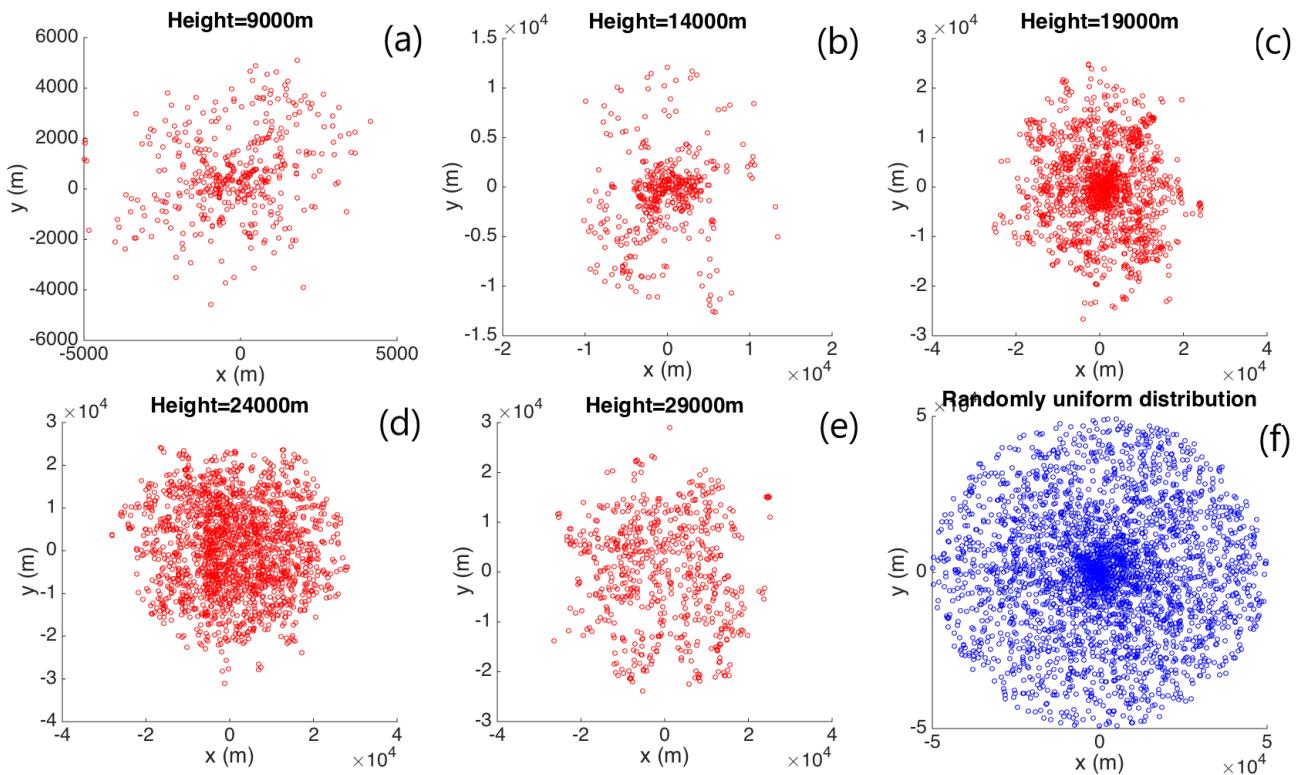

**Figure 7.** Particle distribution of initial ash cloud in vertical direction. (a) is corresponding to the initial ash cloud obtained from Plume-SPH output. (b) is corresponding to ash distribution truncated by a elevation threshold of 15000m. (c) is for vertical ash distribution based on Poisson distribution with maximum height equals to 40000m. Another parameter, the vertical spread, in the expression of Poisson plume shape is 6662m. (d) is corresponding to Suzuki distribution with maximum height equals to 40000m. Another parameter in Suzuki distribution, the shape factor, is 4. The  $x$  axis is the percentage of particle numbers for Plume-SPH and Poisson. For Suzuki the  $x$  axis is the mass percentage of erupted material.

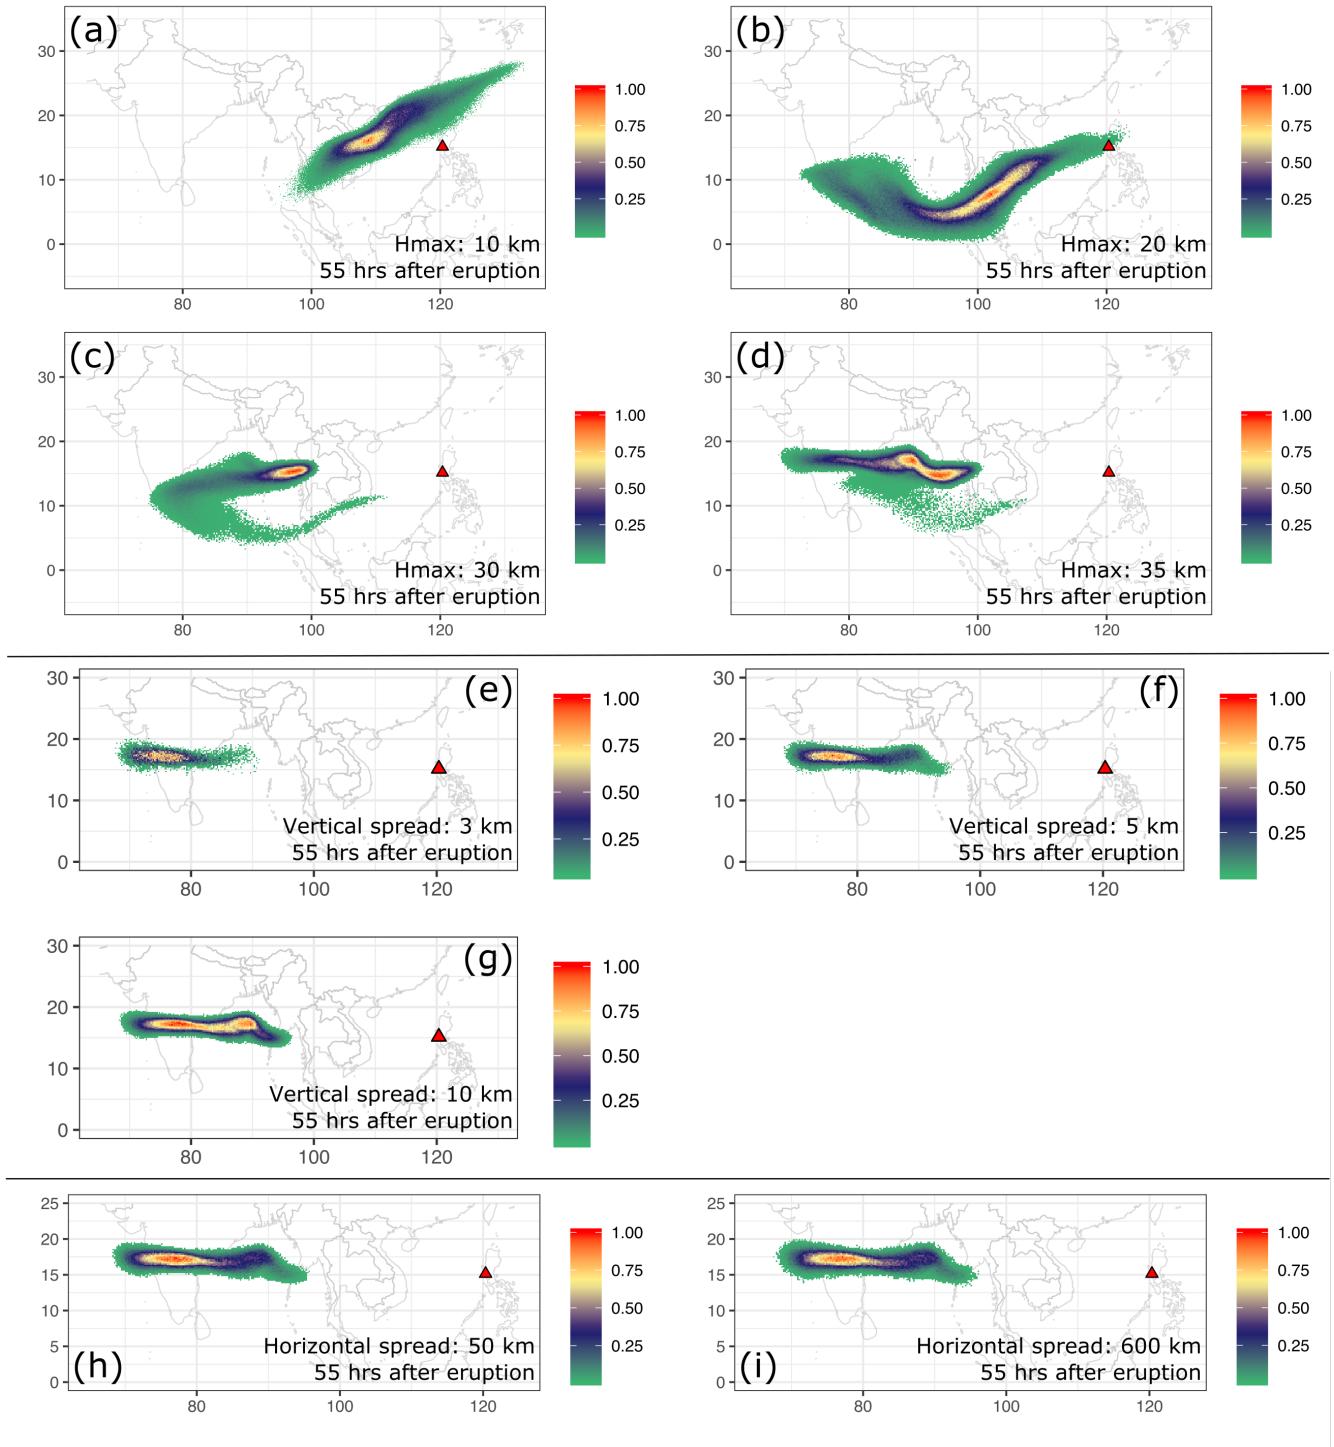

**Figure 8.** Initial particle distribution in vertical direction based on Poisson plume shape. The first row varies maximum heights. (a) to (d) are corresponding to maximum height of 10000m, 20000m, 30000m, 35000m. Another parameter, the vertical spread, in the expression of Poisson plume shape is 6662m for all four figures in the first row. The second row varies “vertical spread”. (e) to (g) are corresponding to vertical spread of 3km, 5km and 10km. The maximum height in the expression of Poisson plume shape is 40000m for all three figures. The  $x$  axis is the percentage of particle numbers. See Fig. 7 for vertical ash distribution of Plume-SPH output.

**Figure 9.** Comparison between radius of initial ash clouds created by 3D plume model (Plume-SPH) and assumed initial ash cloud shape in Puff. The plume shape expression used in Puff defines an inverted cone whose actual shape changes when “horizontal spread” takes different values.  $R = 25\text{km}$  is corresponding to “horizontal spread” equals to  $50\text{km}$ .  $R = 50\text{km}$  is corresponding to “horizontal spread” equals to  $100\text{km}$

**Figure 10.** Horizontal distribution of ash particles (tracers) on a cross section of initial ash cloud. Puff assumes a randomly uniform distribution of ash particles within a circle, as shown by blue dots in (f). All other figures show the ash particle distribution of initial ash clouds created by Plume-SPH at different elevations.

**Figure 11.** Ash transport simulated by Puff using different initial ash clouds created according the empirical expressions. Initial ash cloud for (a) to (d) are created according to Poisson distribution with maximum plume heights of 10km, 20km, 30km and 35km respectively. Initial ash cloud for (e) to (g) are created with vertical spread equals to 3km, 5km and 10km. respectively. Initial ash cloud for (h) - (i) are created with “horizontal spread” equals to 50km and 600km respectively. All images are for simulated ash transport around 55 hours after eruption (UT 199106171141). See the observed cloud image in Fig. 6.
